Performance Goal Text:			

Task Description:	Bedrest is an excellent analog for the study of on-orbit musculoskeletal changes that occur during long-duration spaceflight. Our novel approach involved quantifying typical daily loads to the lower extremities in selected free-living volunteer subjects who are moderate exercisers and planning individual exercise prescriptions based on DLS theory. Subjects were randomized to control or exercise groups and confined to 6-degree head-down bedrest in the General Clinical Research Center (GCRC) at the Cleveland Clinic for 12 weeks. During this time, the exercise group underwent individualized daily exercise programs in the unique Zero Gravity Locomotion Simulator (ZLS) at CCF designed to replace their daily mechanical load stimulus experienced during free living. DXA, MRI, and QCT scans were conducted at the start and end of bedrest to assess variations in bone mineral density, changes in muscle volume, and regional changes (cortical vs. trabecular) in bone. Strength measurements were collected pre- and post-bedrest, and urinary and serum markers of bone resorption and formation were also assessed. Dietary intake sufficient to maintain constant body weight with a balanced intake of macro- and micronutrients was planned and supervised by a registered dietician, and a physician was available 24 hr/day to attend to any medical needs. A rehabilitation program was offered to subjects in the 8 weeks following bedrest. The proposed experiment should provide a categorical answer to the question of whether intermittent load replacement can adequately protect the musculoskeletal system against hypokinetic osteopenia and muscle atrophy and may open a new era in individualized exercise countermeasure planning. This study is in the process of being relocated to the University of Texas Medical Branch (UTMB) in Galveston, TX for completion. All data reported here were collected at the Cleveland Clinic.
Rationale for HRP Directed Research:	
Research Impact/Earth Benefits:	The information obtained as a result of this study will provide further insight into the role of skeletal loading in bone loss during long-duration spaceflight, and knowledge gained from this research will thereby contribute to a better understanding of the importance of exercise for the development and maintenance of bone strength among humans living in Earth gravitational fields. Knowledge in this area is crucial to the treatment of bone disease for which exercise may or may not be an effective intervention.
Task Progress:	Cleveland Clinic GCRC support has continued through this year. Three campaigns were attempted, and four subjects (two controls and two exercisers) successfully completed the study. Though one subject had to be removed from the study due to unrelated medical reasons, it was anticipated that there would be attrition of two subjects in the entire study period and thus the study is still adequately powered. The total number of subjects who have completed the study is now 11 (6 controls and 5 exercisers). As previously mentioned. the team is in the process of moving the study to the University of Texas Medical Branch in Galveston, TX for completion of the remaining 12 subjects. The project team has modified existing mathematical theories on daily load stimulus (DLS) incorporating new theories on saturation and recovery of the osteogenic potential of bone with distributed mechanical loading and the effects of standing. This revised algorithm has been dubbed the enhanced DLS (eDLS). Extensive MATLAB code has been written to allow users to analyze complete sets of in-shoe force data and calculate eDLS. The eDLS is being used to formulate the individualized exercise prescriptions used by the exercising subjects. The eDLS algorithm has been documented and submitted to the journal "Aviation, Space, and Environmental Medicine" for publication.
