Performance Goal Text:			

Task Description:	Several substantial medical barriers to long-term space travel include radiation damage, weightlessness, and stress caused by the specialized spacecraft environment. This Human Exploration Research Opportunities (HERO) grant solicitation requests applicants to take advantage of the unusual opportunity to compare identical twins, one of whom will be traveling in orbit for a year while the other will remain on Earth. The area of science that most directly addresses this opportunity is epigenetics, the study of chemical changes to DNA and the associated proteins, other than the DNA sequence itself. Our laboratory is the leading center that has pioneered the methods for analyzing epigenetics at a genome-scale level, termed epigenomics, and for applying these methods to the discovery of epigenetic causes and mediators of common human disease. These discoveries include the first analysis of epigenomic changes in individuals over time, the first complete epigenomic map of human cancer, the discovery of an epigenomic basis for autoimmune disease, and epigenomic mechanisms for injury response. In this proposal, we will test the hypothesis that space-induced exposure causes epigenome damage. We will determine the nature of this damage, and whether it is correctible spontaneously. We will measure three epigenome-related modalities in identical twins, namely: DNA methylation, a chemical change in the base cytosine; large heterochromatin regions related to chemical modifications of histones; and their functional relationship to gene expression of RNA (expression data generated by other Twins' investigators). We will obtain measurements prior to launch, after reentry, and at quarterly intervals in space, as well as after any unforeseen environmental exposure such as a spike in radiation. We will complement this analysis with whole genome DNA sequencing data generated by other Twins' researchers before and after the flight on both twins, in order to relate epigenomic damage to subsequent DNA damage. Given the potentially reversible nature of epigenetic changes, this work may help to identify or mitigate exposure to radiation, weightlessness, and environmental stressors, which are considered the greatest barriers to long term space flight. Thus our work could have a huge impact on long-duration space travel, if we can identify potentially reversible epigenetic precursors of genetic damage to astronauts.
Rationale for HRP Directed Research:	
Research Impact/Earth Benefits:	
Task Progress:	The Principal Investigator (PI) and his staff have spent considerable effort optimizing protocols for cell fractionation, DNA and chromatin analysis, and sequencing. From blood samples collected from each twin throughout the study, we have isolated several classes of immune cells (CD4, CD8, and CD19 positive lymphocyte cells) for epigenome analyses. Helper T cells (CD4+) work together with killer T cells (CD8+) to combat and destroy infected or cancerous cells. B cells (CD19+) make antibodies to respond to these infections. We have also collected buccal and saliva samples that await sequencing. To date, we have performed whole genome bisulfite sequencing (WGBS) on CD4+ and CD8+ cells from 4 time points in each twin, to measure DNA methylation at a genome-wide scale. Novel mathematical modeling tools we recently developed allow us to examine paired samples to identify regions of the genome where the epigenome differs in a meaningful way. Using these methods, we have interrogated our data for epigenetic changes that arose during Scott Kelly's time in space and returned (or not) to baseline levels upon his return. Globally, these changes were minimal when compared to those in Mark Kelly over the same time period. Therefore, we conclude that gross epigenetic changes detected in CD4+ and CD8+ cells from Scott are well within the "normal" range of variation seen in his Earth-bound twin. That being said, we have characterized these small methylation changes in Scott summarized here. We analyzed the following CD4+ and CD8+ samples analyzed via WGBS: Mark – pre-flight (12/3/14), in-flight (7/30/15 and 1/20/16), post-flight (7/17/16); and for Scott – pre-flight (10/16/14), in-flight (6/11/15 and 12/12/15), post-flight (6/14/16). We found subtle, but global differences in genome-wide DNA methylation. DNA methylation is very similar in twins pre-flight. In CD4+ cells, Scott's global DNA methylation is decreased in-flight and returns to near baseline upon return. In contrast, there is a slight increase in global methylation in CD8+ samples collected in-flight that returns to baseline. Mark's global DNA methylation level showed the greatest increase from the first to the second "in-flight" time point in both CD8+ and CD4+ samples (2.4% and 2.7% increase, respectively) before returning to near baseline. Visualization of all gene promoters revealed no detectable changes in methylation throughout the duration of the study for either subject. To identify particular genes displaying differential epigenetic regulation, we calculated the Jensen-Shannon distance (JSD) among all possible pairwise comparisons to quantify the epigenetic discordance between samples. These large Jensen-Shannon distances indicate that, although there may only be small changes in mean methylation levels, there are pronounced changes in the probability distributions of methylation levels in these regions.
